

# Extractor Codes

Amnon Ta-Shma and David Zuckerman, *Member, IEEE*

**Abstract**—We study error-correcting codes for highly noisy channels. For example, every received signal in the channel may originate from some half of the symbols in the alphabet. Our main conceptual contribution is an equivalence between error-correcting codes for such channels and extractors. Our main technical contribution is a new explicit error-correcting code based on Trevisan’s extractor that can handle such channels, and even noisier ones. Our new code has polynomial-time encoding and polynomial-time soft-decision decoding. We note that Reed–Solomon codes cannot handle such channels, and our study exposes some limitations on list decoding of Reed–Solomon codes. Another advantage of our equivalence is that when the Johnson bound is restated in terms of extractors, it becomes the well-known Leftover Hash Lemma. This yields a new proof of the Johnson bound which applies to large alphabets and soft decoding.

Our explicit codes are useful in several applications. First, they yield algorithms to extract many hardcore bits using few auxiliary random bits. Second, they are the key tool in a recent scheme to compactly store a set of elements in a way that membership in the set can be determined by looking at only one bit of the representation. Finally, they are the basis for the recent construction of high-noise, almost-optimal rate list-decodable codes over large alphabets [1].

**Index Terms**—Extractor codes, extractors, hardcore bits, Johnson bound, list decoding, Reed–Solomon codes, soft-decision decoding.

## I. INTRODUCTION

CONSIDER a channel over a large alphabet  $\Sigma$  such that upon sending  $(\sigma_1, \dots, \sigma_T) \in \Sigma^T$ , the receiver is only able to determine sets  $\mathcal{S}_i \subseteq \Sigma$ ,  $|\mathcal{S}_i| = \frac{|\Sigma|}{2}$ , such that  $\sigma_i \in \mathcal{S}_i$ . Can we find codes for which the number of codewords  $(v_1, \dots, v_T)$  such that for all  $i$ ,  $v_i \in \mathcal{S}_i$ , is small? What if we require  $v_i \in \mathcal{S}_i$  for only 51% of  $i$ ?

This scenario has been raised before in the context of list decoding. If we allow more than half the distance  $d$  errors, then guaranteed unambiguous decoding is impossible. List decoding tries to rectify this situation. We give up on guaranteed unambiguous decoding and instead we require that the number of codewords with modest agreement with the received word is

small (and in the algorithmic version we output all these codewords). Thus, an adversary choosing  $\frac{d}{2}$  errors may force ambiguous decoding, but will never be able to make this ambiguity large. A useful view of this is that the number of codewords in any large ball is small.

Although list decoding was defined independently by Elias [2] and Wozencraft [3] in the 1950s, no nontrivial list decoding algorithm was known until the late 1980s. Since then, there have been several [4]–[7]. For an excellent survey paper and for the history of the list decoding problem, we refer the reader to [8], and Section 3.3 therein in particular.

As it turns out, the list decoding algorithms above deal also with the case where for each  $i$  the receiver has a *small* set  $\mathcal{S}_i$  of possible explanations of the  $i$ th symbol. In fact, Guruswami and Indyk [9] subsequently called the natural generalization of this property “list-recoverable,” and showed how to use this property of Reed–Solomon codes to build better list-decodable codes. A natural question is then, can one find such a code for the case where the sets  $\mathcal{S}_i$  are large?

We first show that when the sets  $\mathcal{S}_i$  are large, Reed–Solomon codes could have exponentially many codewords such that for all  $i$ ,  $v_i \in \mathcal{S}_i$ . Thus, Reed–Solomon codes are not a good choice for such a scenario. In contrast, we exhibit codes with only polynomially many codewords having 51% of the  $v_i \in \mathcal{S}_i$ , even when the errors are picked adversarially. This property also holds in the soft-decision model. We give explicit codes that have polynomial-time encoding and list decoding, and nonexplicit codes with better parameters.

Our codes are based upon a combinatorial object from the study of pseudorandomness called an extractor. An extractor is a procedure that extracts randomness from a defective random source, using a small additional number of truly random bits. Extractors were first defined and constructed in [10], and have since been improved by several authors. Extractors have been used to construct various types of pseudorandom generators ([10]–[12]), and have had important applications in seemingly unrelated areas, including expander graph and superconcentrator constructions [13], time–space tradeoffs [14], and unapproximability [15], [16]. See [17]–[19] for surveys of extractors.

This paper gives yet another unexpected application of extractors. We show an equivalence between extractors and codes which decode in highly noisy channels in the adversarial model. This equivalence implies bounds on the parameters such codes must have. For instance, the rate of such codes must be smaller than  $\frac{1}{\log|\Sigma|}$ , and there is a word with at least  $\Omega\left(\frac{|\Sigma|}{n}\right)$  close codewords.

This equivalence also sheds light on the Johnson bound [20]. Restated in terms of extractors, the Johnson bound becomes the

well-known Leftover Hash Lemma. This yields a new proof of the bound which applies to large alphabets and soft decoding.

Our explicit codes are based on Trevisan's explicit extractor [21]. We show that it has polynomial-time encoding, polynomial-time list decoding, and is capable of handling the above noisy channel even in the adversarial model. Thus, we build an explicit code that has better soft-decision list decoding than Reed–Solomon, and can tolerate much more noise.

These explicit codes can be used to extract hardcore bits, a very useful tool in cryptography and the earliest application of list decoding in computer science [4]. We are able to extract many hardcore bits using few auxiliary random bits.

## II. TOP DOWN OVERVIEW

### A. Soft-Decision Decoding

In reality, channel noise is almost always a continuous phenomenon. Thus, on receiving a signal  $\sigma$  the detector may decide that the transmitted symbol was  $a_1$  with probability  $\frac{98}{100}$ ,  $a_2$  with probability  $\frac{1}{100}$ , and  $a_3$  with probability  $\frac{1}{100}$ . A hard-decision detector may transform the signal  $\sigma$  to the symbol  $a_1$ . Soft-decision decoding tries to use these probabilities.

Early attempts at soft-decision decoding start with Forney's generalized minimum-distance (GMD) decoding [22]. Recent soft-decoding algorithms include [23] for Reed–Solomon codes and [24] for Chinese Remainder codes. Some of these papers (e.g., [24]) study a soft-decision detector that outputs a single  $\Sigma$  symbol along with a confidence level, thus using only some of the information the channel contains. We now formally define soft decoding.

When we receive a symbol from a noisy channel, we can infer a probability distribution over all possible symbols in the alphabet  $\Sigma = [M]$ . We deal with time-varying channels; seeing a symbol  $\sigma \in [M]$  at time  $i \in [T]$  induces a weight function  $w_i : [M] \rightarrow [0, 1]$ , where  $w_i(z)$  corresponds to the probability that the  $i$ th transmitted symbol is  $z$  given that the  $i$ th received symbol is  $\sigma$ .

In fact, we can also deal with noisy channels where seeing the whole sequence  $\sigma_1, \dots, \sigma_T \in [M]^T$  induces a *product* weight function  $w : [T] \times [M] \rightarrow [0, 1]$ , where  $w(i, z)$  corresponds to the probability that the  $i$ th transmitted symbol is  $z$  when receiving  $\sigma_1, \dots, \sigma_T$ . Notice also, that the weight function may be arbitrary, and in particular does not have to sum up to 1. As we work with bounded accuracy we assume  $w(i, y)$  is always a multiple of  $\frac{1}{M}$ . For normalization, we define the relative weight of  $w$  as

$$\rho(w) = \frac{\sum_{i \in [T], y \in [M]} w(i, y)}{TM}.$$

Notice that  $\rho(w)$  is a real number between zero and one.

We call the elements of  $[T] \times [M]$  *points*. We view a word  $u \in [M]^T$  as the set of points  $\{(i, u_i) : i \in [T]\}$ . The *agreement*  $\text{Ag}(u, w)$  between a word  $u$  and a weight function  $w$  is the sum of the weights of the points corresponding to  $u$ , i.e.,  $\sum_{i \in [T]} w(i, u_i)$ . The case where  $w$  takes on only Boolean values is of special interest, as then  $w$  corresponds to sets. For sets  $\mathcal{S}_1, \dots, \mathcal{S}_T \subseteq [M]$ ,  $\text{Ag}(u, (\mathcal{S}_1, \dots, \mathcal{S}_T)) = \text{Ag}(u, w)$ ,

where  $w$  is the indicator weight function  $w(i, \sigma) = 1$  if  $\sigma \in \mathcal{S}_i$  and 0 otherwise. When the sizes of the  $\mathcal{S}_i$  are 1 this amounts to the usual notion of agreement between two vectors.

Now, let  $\mathcal{C} = \{\mathcal{C}_r\}$  be a family of codes, where  $\mathcal{C}_r \subseteq [M]^T$  is a code of length  $T = T(r)$  over alphabet  $[M] = \{1, 2, \dots, M\}$ ,  $M = M(r)$ . We use unconventional letters for describing the alphabet and the code length so as to avoid  $n, N, k, K$ , and  $d, D$  which are standard for both extractors and coding theory. We say the family  $\mathcal{C}$  has efficient encoding if there is a polynomial-time algorithm that given  $r$  and  $j$  computes the  $j$ th codeword of  $\mathcal{C}_r$  in time  $\text{poly}(M, T)$ . When it is clear from the context we say that  $\mathcal{C}$  has efficient encoding.

The list decoding problem comes in two flavors, combinatorial and algorithmic. In both we are given an arbitrary weight function  $w$ , which is the essence of the adversarial model. The combinatorial version is to bound the *number* of codewords that have large agreement with  $w$ , while the algorithmic version is to actually find all these codewords. Note that the expected agreement of a random word from  $[M]^T$  with  $w$  is  $\rho(w)T$ ; by large agreement we mean noticeably larger than this, as is captured in the definition of  $\mathcal{A}_\epsilon$  that follows.

*Definition II.1:* We say a code  $\mathcal{C}_r \subseteq [M]^T$  has  $(L, \epsilon)$  combinatorial soft decoding if for every weight function  $w : [T] \times [M] \rightarrow [0, 1]$  the set

$$\mathcal{A}_\epsilon(w) = \{u \in \mathcal{C} : \text{Ag}(u, w) > (\rho(w) + \epsilon)T\}$$

has size at most  $L$ . We say a family of codes  $\mathcal{C} = \{\mathcal{C}_r\}$  has  $(L = L(r), \epsilon = \epsilon(r))$  combinatorial soft decoding if for all  $r$ ,  $\mathcal{C}_r$  has  $(L(r), \epsilon(r))$  soft decoding. If  $L(r) \leq p(T, M, \frac{1}{\epsilon})$  for some polynomial  $p(\cdot)$  we simply say  $\mathcal{C}$  has  $\epsilon$  combinatorial soft decoding.

In the algorithmic version we want efficient decoding. That is, we have a noisy channel, and we see  $\sigma_1, \dots, \sigma_T$  which induces a weight function  $w : [T] \times [M] \rightarrow [0, 1]$ . We give the decoding algorithm black-box access to  $w$ , and we want to recover the original codeword.

*Definition II.2:* We say a family  $\{\mathcal{C}_r\}$  has efficient  $\epsilon$  soft decoding if there exists an algorithm that given black-box access to the weight function  $w$  outputs all the codewords in  $\mathcal{A}_\epsilon(w)$  in time polynomial in  $T, M, \frac{1}{\epsilon}$ .

We say a family  $\{\mathcal{C}_r\}$  has efficient *probabilistic*  $\epsilon$  soft decoding, if the decoding algorithm is probabilistic, and for every weight function  $w$ , with probability at least  $1 - 2^{-(M+T)}$  over its internal random coins, outputs all the codewords in  $\mathcal{A}_\epsilon(w)$  in time polynomial in  $T, M, \frac{1}{\epsilon}$ .

We also define  $\mathcal{A}_{\max}(w)$  to be the set of codewords  $u \in \mathcal{C}$  that have full agreement with  $w$ , i.e.,

$$\mathcal{A}_{\max}(w) = \{u \in \mathcal{C} : \text{Ag}(u, w) = T\}.$$

<sup>1</sup>Notice that we can represent a weight function  $w : [T] \times [M] \rightarrow [0, 1]$  with  $MT$  numbers, each a multiple of  $\frac{1}{M}$ , and hence with  $\text{poly}(T, M)$  bits. Thus, we could have replaced the above definition with one that says that given a description of  $w$  the algorithm outputs all codewords in  $\mathcal{A}_\epsilon(w)$  in time  $\text{poly}(T, M, \frac{1}{\epsilon})$ . However, in many settings the black-box version is more natural.

## B. Strong Extractors

As mentioned earlier, an extractor is a procedure to extract randomness from a defective random source, using a small additional number of truly random bits. In order to define extractors, we first give some standard definitions.

*Definition II.3:* A probability distribution  $D$  on  $\Omega$  is a function  $D : \Omega \rightarrow [0, 1]$  such that  $\sum_{x \in \Omega} D(x) = 1$ . For an integer  $n$ ,  $U_n$  is the uniform distribution on  $\{0, 1\}^n$ . We overload notation and for a set  $S$ ,  $U_S$  denotes the uniform distribution on  $S$ . The variation (statistical) distance between two probability distributions  $D_1$  and  $D_2$  on  $\Omega$ , denoted  $|D_1 - D_2|$ , is

$$\frac{1}{2} \sum_{x \in \Omega} |D_1(x) - D_2(x)| = \max_{S \subseteq \Omega} |D_1(S) - D_2(S)|.$$

We say  $D_1$  is  $\epsilon$ -close to  $D_2$  if  $|D_1 - D_2| \leq \epsilon$ . A distribution on a set  $S$  is  $\epsilon$ -uniform if it is  $\epsilon$ -close to  $U_S$ .

We model a defective random source as one that has sufficient min-entropy, a notion that is more useful to us than entropy.

*Definition II.4:* The *min-entropy* of a distribution  $D$  is  $\min_x \log_2 1/D(x)$ .

In other words,  $D$  has min-entropy  $\ell$  if for all  $x$ ,  $D(x) \leq 2^{-\ell}$ . We now define extractors, using slightly different parameters than usual (typically the  $L$  below is replaced by  $\log L$ ).

*Definition II.5:* A function  $E : [C] \times [T] \rightarrow [M]$  is a strong  $(L, \epsilon)$ -extractor if for every distribution  $D$  on  $[C]$  such that for all  $x$ ,  $D(x) \leq 1/L$ , the distribution  $U_T \circ E(D, U_T)$  obtained by picking  $x$  from  $D$ ,  $y$  uniformly from  $[T]$  and evaluating  $y \circ E(x, y)$  is  $\epsilon$ -uniform. Here,  $\circ$  denotes concatenation. ( $E$  is an extractor if  $E(D, U_T)$  is  $\epsilon$ -uniform.)

In other words, for any test  $W : [T] \times [M] \rightarrow \{0, 1\}$ , the probability that  $W(y, z) = 1$  is roughly the same whether  $y$  and  $z$  are chosen uniformly, or  $y$  is chosen uniformly and  $z = E(x, y)$  for  $x$  chosen with sufficient min-entropy. Note that there is no constraint on the efficiency of the test; in fact, the test can be randomized, as a randomized test can be viewed as randomly picking one of several deterministic tests.

A natural interpretation for this is that

$$E : \{0, 1\}^c \times \{0, 1\}^t \rightarrow \{0, 1\}^m$$

is a strong  $(L = 2^\ell, \epsilon)$  extractor, if it takes an arbitrary distribution over  $[C] = \{0, 1\}^c$  with at least  $\ell$  min-entropy (this corresponds to  $X \subseteq [C]$  of cardinality at least  $L$ ), uses  $t$  independent truly random bits, and distills from  $X$   $m$  output bits that are close to uniform (this corresponds to the fact that no test can distinguish  $U_T \circ E(D, U_T)$  from uniform). We would like, of course, to have  $t$  as small as possible and  $m$  as close as possible to  $\ell$ .

We now define efficiency of extractors; first, we give the usual notion and then a weaker version which will suffice for our purposes.

*Definition II.6:* An extractor  $E : [C] \times [T] \rightarrow [M]$  is efficient if it is computable in time polynomial in  $\log T + \log M + \log C$ .

It is weakly efficient if it is computable in time polynomial in  $T + \log M + \log C$ .

## C. The Equivalence to Extractors

We associate a code with a strong extractor:

*Definition II.7:* Let  $E : [C] \times [T] \rightarrow [M]$  be a strong extractor. For each  $c \in [C]$ , define a word  $z(c) = (z_1, \dots, z_T) \in [M]^T$  where  $z_i = E(c, i)$ . The extractor code for  $E$  is

$$\mathcal{C}_E = \{z(c) \in [M]^T \mid c \in [C]\}.$$

The next theorem shows that strong extractors give codes with good soft decoding, and that these two notions are, in fact, equivalent.

*Theorem 1:* If  $E : [C] \times [T] \rightarrow [M]$  is a strong  $(L, \epsilon)$  extractor, then  $\mathcal{C}_E$  has  $(L, \epsilon)$  combinatorial soft decoding. Conversely, if  $\mathcal{C}_E$  has  $(L, \epsilon)$  combinatorial soft decoding, even if only with respect to Boolean weight functions, then  $E$  is a strong  $(\frac{L}{\epsilon}, 2\epsilon)$  extractor. Finally,  $\mathcal{C}_E$  has efficient encoding if and only if  $E$  is weakly efficient.

Note that this theorem also implies that combinatorial soft decoding with respect to Boolean weight functions implies general combinatorial soft decoding with only a slight degrading of parameters.

By efficient encoding, we mean that the encoding time is polynomial in the encoded length  $T \log M \geq \log C$ . Therefore, the last statement in the theorem about efficiency is obvious, since encoding in  $\mathcal{C}_E$  amounts to computing  $E$  at  $T$  different points.

Typically, we will consider large alphabets:  $M \geq T^{\Omega(1)}$  or larger. (An exception is when we consider the Johnson bound.) In this typical case, if we want the size  $L$  of the solution list to be polynomial in  $M$  (so that we have  $\epsilon$ -combinatorial list decoding) the extractor  $E$  has to extract at least a constant fraction of the min-entropy in the given source. That is, if we denote  $L = 2^\ell$  (i.e., the given source  $X$  has  $\ell$  min-entropy) and  $M = 2^m$  (i.e., the extractor extracts  $m$  bits that are close to uniform) then  $L \leq M^{\Omega(1)}$ , or equivalently  $M \geq L^\alpha$  for some constant  $\alpha$ , i.e.,  $m = \Omega(\ell)$ .

Although a good extractor yields a code with good soft decoding and efficient encoding, usually we do not have efficient decoding for such codes. Getting codes with explicit encoding and decoding is a main goal of this paper, and we will later show how to achieve it.

The connection between extractors and error-correcting codes sheds light on the Johnson bound [20], which states that a binary code with relative distance  $\frac{1}{2} - \delta$  has the property that every ball of relative radius  $\frac{1}{2} - \sqrt{\delta}$  contains at most  $1/\delta$  codewords (the bound was generalized to larger fields in [25]). Typically, the Johnson bound is the key tool used to determine the quality of combinatorial list decoding in the traditional sense. The Johnson bound, however, does not generalize to the soft-decision setting (e.g., to the setting where all we know is that the  $i$ th transmitted symbol is one of  $\frac{|S_i|}{2}$  possibilities).

The Johnson bound was given several proofs; some of the more recent ones include a proof with geometric motivation in

[26], a proof using inclusion–exclusion in [25] and a combinatorial proof using the Zarankiewicz bound in [27]. We, however, interpret the Johnson bound as saying that a good code is a good extractor, and we give it a simple proof that is identical to the simple proof of the Leftover Hash Lemma [28]. In Lemma IV.1 we show that our interpretation does generalize to the soft-decision setting.

We also use the equivalence with extractors to derive bounds on soft decoding. A lower bound of [29] says that a strong  $(L, \epsilon)$  extractor  $E : [C] \times [T] \rightarrow [M]$  must have

$$T \geq \Omega\left(\frac{\log\left(\frac{C}{L}\right)}{\epsilon^2}\right) \quad (1)$$

and

$$L \geq \Omega\left(\frac{M}{T} \cdot \frac{1}{\epsilon^2}\right). \quad (2)$$

Furthermore, random extractors, with high probability, almost match these bounds [29]. The equivalence of Theorem 1 translates this to nonexplicit codes  $\mathcal{C}_E \subseteq [M]^T$  with  $(L, \epsilon)$  soft decoding and  $|C|$  codewords. The bound (1) then tells us how far we can push the rate of this code. Namely, the rate is  $\frac{\log(C)}{T \log(M)}$  which is about  $\frac{\epsilon^2}{\log(M)}$  as long as  $L$  is much smaller than  $C$ . The bound (2) tells us that as long as the code length  $T$  is much smaller than the alphabet size  $M$ , the number of possible solutions cannot be constant. Anything is achievable within these bounds. In particular, there are codes with many codewords and  $(L, \epsilon)$  soft decoding for a relatively small  $L = \text{poly}\left(M, T, \frac{1}{\epsilon}\right)$ .

#### D. Reed–Solomon Codes

There has been a lot of research on efficiently encoding and decoding Reed–Solomon codes. We first state the beautiful list decoding result of Guruswami and Sudan [6] building upon Sudan [5].

*Theorem 2:* [6] Let  $\mathcal{RS} \subseteq [M]^T$  be a Reed–Solomon code,  $T \leq M$ ,  $|\mathcal{RS}| = M^c$ . For every  $\mathcal{S}_1, \dots, \mathcal{S}_T \subseteq [M]$

$$\left| \left\{ U \in \mathcal{RS} \mid \text{Ag}(u, (\mathcal{S}_1, \dots, \mathcal{S}_T)) \geq \sqrt{cS} \right\} \right| \leq T$$

where  $S = \sum_{i=1}^T |\mathcal{S}_i|$ . Furthermore,  $\mathcal{RS}$  has efficient list decoding for these parameters.

Note that the bound is very good when  $S$  is small (say, about  $T$ ) and that it deteriorates as  $S$  grows. In particular, it is useless whenever  $\sqrt{cS} > T$  (e.g., if  $M = T$  and  $S = \frac{MT}{2}$ ). Restated in our soft-decoding notation, the list decoding algorithm works well as long as  $\rho(w)$  is small (about  $\frac{1}{M}$ ), and is not guaranteed to work when  $\rho(w)$  is large (a constant). We show that this phenomenon is not an artifact of the analysis but rather Reed–Solomon codes indeed have poor list decoding when  $\rho(w)$  is large.

*Theorem 3:* Let  $\mathcal{RS} \subseteq [M]^T$  be a Reed–Solomon code with  $M^c$  elements,  $T \leq M$ , and  $M$  a prime power. Suppose  $M - 1 = b_1 b_2$  for some integers  $b_1$  and  $b_2$ . Then, there is a Boolean weight function  $w : [T] \times [M] \rightarrow \{0, 1\}$  with weight  $\rho(w) = \frac{b_1 + 1}{M}$  for which  $|\mathcal{A}_{\max}(w)| \geq M^{\frac{\epsilon - 1}{b_2}}$ .

Thus, in particular, for  $b_2 = 2$  we get a Boolean weight function of weight about half, for which there are about  $\sqrt{|\mathcal{RS}|}$  close codewords. Also, notice how the number of codewords in the bound decays with the relative weight of  $w$ .

#### E. An Extractor Code With Efficient Soft Decoding

We saw that good extractors  $E$  translate to codes  $\mathcal{C}_E$  with good combinatorial soft decoding; in particular, if  $E$  extracts a constant fraction of the min-entropy of the given source (i.e.,  $m \geq \Omega(\ell)$ ) and has error  $\epsilon$ , then  $\mathcal{C}_E$  has  $\epsilon$  combinatorial soft decoding. Nevertheless, not every good extractor suits our needs, as  $\mathcal{C}_E$  might not have *efficient* soft decoding. Our main technical contribution is showing that block-box pseudorandom generator constructions translate to codes with efficient soft decoding. In Section VI, we explain in detail the notion of block-box pseudorandom generator, and show that every code that originates from such a construction has efficient *probabilistic* soft decoding. In Section VII, we show how to make the decoding algorithm deterministic for one such code.

Currently, there are two black-box pseudorandom generator constructions: Trevisan’s construction [21] and Shaltiel and Umans’s construction [30].

- Trevisan’s extractor extracts half of the min-entropy in the source using  $t = O(\log^2(\frac{c}{\epsilon}))$  truly random bits, hence its corresponding code  $\mathcal{C}_{\text{TR}} \subseteq [M]^T$  has  $\epsilon$  combinatorial soft decoding. Its rate is

$$\frac{\log(C)}{T} \frac{1}{\log(M)} = \frac{1}{2^{(\log \log(\frac{c}{\epsilon}))^2}} \frac{1}{\log(M)}$$

which should be compared to the best possible rate of about  $\frac{\epsilon^2}{\log(M)}$ . This reflects the fact that Trevisan’s extractor has degree larger than optimal. Nevertheless, we still accommodate exponentially many codewords into  $[M]^T$ .

- Shaltiel and Umans’s extractor extracts a subconstant fraction of the min-entropy in the source,  $m = \frac{\ell}{\text{poly} \log(c)}$ , using only  $O(\log(\frac{c}{\epsilon}))$  truly random bits. Hence, its corresponding code  $\mathcal{C}_{\text{SU}} \subseteq [M]^T$  has  $(L, \epsilon)$  combinatorial soft decoding for a super-polynomial  $L = M^{\text{poly}(\log \log(C))}$ . Its rate is

$$\frac{\log(C)}{T} \frac{1}{\log(M)} = \frac{1}{2^{\log \log(\frac{c}{\epsilon})}} \frac{1}{\log(M)}$$

which compares better to the lower bound which is about  $\frac{\epsilon^2}{\log(M)}$ .

Any future better black-box extractor construction would immediately translate to a better code. In particular, if such a construction is found with  $m = \Omega(\ell)$  and  $T = \Omega\left(\frac{\log(C)}{\epsilon^2}\right)$  then we would get a code with efficient  $\epsilon$  soft decoding and almost optimal rate.

One special case of interest is when  $T = M$  which is similar to the Reed–Solomon case. It turns out that Trevisan’s code has soft decoding for exponentially small  $\epsilon$ . In fact,  $\epsilon$  can be as small as  $2^{-\Omega(\sqrt{\log M})}$ . On the other hand, Reed–Solomon codes do not have soft decoding for any  $\epsilon > 0$ . We again demonstrate this

with the case where given a signal the receiver can only guess the transmitted symbol is one of  $\frac{|\Sigma|}{2}$  possible symbols. The code  $\mathcal{C}_{\text{TR}}$  we presented can recover the original symbol even if just slightly over half the guesses are correct (half is what you expect from a random guess) whereas for Reed–Solomon codes there is no way to recover the original symbol even if every guess is always correct.

### F. Applications

The first application of list decoding [4] was obtaining hardcore bits, though it was not observed to be a list decoding algorithm at the time. For this application, soft list decoding is more useful than ordinary list decoding. Using our codes, we can output many hardcore bits while adding only few auxiliary random bits. In Section VIII, we explain the problem, previous work, and our result.

Recently, the results of this paper were used in [31] to give an explicit space-efficient method of storing a set of elements from a large universe in such a way that membership in the set can be determined (with high probability) by reading only one bit from the set representation. For the history of the problem, and the extensive previous work on it we refer the reader to [32].

### III. EQUIVALENCE OF EXTRACTORS AND SOFT DECODING

We now prove Theorem 1, the equivalence of extractors and codes with good soft decoding. The proof makes use of an alternate view of extractors suggested in [11], where for a given test the number of “bad” strings for this test is small.

*Proof: (of Theorem 1):*

$E$  strong extractor  $\implies \mathcal{C}_E$  has soft decoding:

Suppose  $E : [C] \times [T] \rightarrow [M]$  is a strong  $(L, \epsilon)$  extractor. Let  $w : [T] \times [M] \rightarrow [0, 1]$  be a weight function for the code  $\mathcal{C}_E \subseteq [M]^T$ . Define the test  $W : [T] \times [M] \rightarrow \{0, 1\}$  which accepts  $(i, y)$  with probability  $w(i, y)$ . Then

$$\Pr[W(U_{[T] \times [M]}) = 1] = \frac{\sum_{i,y} w(i,y)}{\text{TM}} = \rho(w).$$

We wish to show that the set  $\mathcal{A} = \mathcal{A}_\epsilon(w)$  is small.

For a set  $X \subseteq [C]$ , let  $D_{E,X}$  be the distribution obtained by picking  $x$  uniformly from  $X$ ,  $y$  uniformly from  $T$  and evaluating  $y \circ E(x, y)$ . By the definition of  $\mathcal{A}$

$$\Pr[W(D_{E,\mathcal{A}}) = 1] > \rho(w) + \epsilon.$$

Hence,  $D_{E,\mathcal{A}}$  is not  $\epsilon$ -uniform, so by the extractor definition we must have  $|\mathcal{A}| \leq L$ .

$\mathcal{C}_E$  has soft decoding  $\implies E$  is a strong extractor:

Fix a test  $W : [T] \times [M] \rightarrow \{0, 1\}$ . As  $\mathcal{C}_E$  has  $(L, \epsilon)$  soft decoding, for at most  $L$  values of  $x \in [C]$

$$\Pr[W(D_{E,\{x\}}) = 1] > \Pr[W(U_{[T] \times [M]}) = 1] + \epsilon.$$

Now let  $D$  be an arbitrary distribution on  $[C]$  with  $D(x) \leq \epsilon/L$  for all  $x$ . Then

$$\Pr[W(U_T \circ E(D, U_T)) = 1] \leq \Pr[W(U_{[T] \times [M]}) = 1] + 2\epsilon$$

since the  $L$  “bad”  $x$  only account for probability at most  $\epsilon$ .

As this is true for every test  $W$ , and in particular for the test  $W'$  that negates  $W$ , we must have

$$|\Pr[W(U_T \circ E(D, U_T)) = 1] - \Pr[W(U_{[T] \times [M]}) = 1]| \leq 2\epsilon.$$

Hence,  $E$  is a strong  $(\frac{L}{\epsilon}, 2\epsilon)$  extractor.  $\square$

### IV. THE JOHNSON BOUND

We start with the well known claim that codes with good distance properties are reasonable extractors:

*Claim IV.1:* (Codes are extractors) Let  $\mathcal{C}$  be a

$$\left[ T, k, \left( 1 - \frac{1}{q} - \delta \right) T \right]_q$$

code. Let  $E : \mathbb{F}_q^k \times [T] \rightarrow \mathbb{F}_q$  be the function  $E(x, i) = \mathcal{C}(x)_i$ . Then  $E$  is a  $(\frac{1}{\delta}, \sqrt{\frac{q\delta}{2}})$  extractor.

*Proof:* We follow Rackoff’s proof of the Leftover Hash Lemma as in [33]. Let  $X \subseteq \mathbb{F}_q^k$  be of cardinality  $\frac{1}{\delta}$ , and recall that  $D_{E,X}$  is the distribution obtained by picking  $y$  uniformly from  $[T]$ ,  $x$  uniformly from  $X$ , and evaluating  $y \circ E(x, y)$ .

The collision probability of  $D_{E,X}$ , denoted  $\text{col}(D_{E,X})$ , is the probability that two independent samples of the distribution  $D_{E,X}$  are the same. It is therefore the probability over  $y_1, y_2 \in [T]$  and  $x_1, x_2 \in X$  that  $y_1 = y_2$  and  $E(x_1, y_1) = E(x_2, y_2)$ . Obviously, we should have  $y_1 = y_2$ . If we also have  $x_1 = x_2$  then we get a collision. From the large distance of the code  $\mathcal{C}$  it follows that if  $x_1 \neq x_2$  we have probability (over  $y = y_1 = y_2$ ) of at most  $\frac{1}{q} + \delta$  of having a collision. Altogether

$$\begin{aligned} \text{col}(D_{E,X}) &\leq \frac{1}{T} \left( \frac{1}{|X|} + \frac{1}{q} + \delta \right) \\ &= \frac{1}{qT} \left( 1 + \frac{q}{|X|} + q\delta \right). \end{aligned}$$

Rackoff shows that if  $D$  is distributed over some domain  $\Omega$  and  $\text{col}(D) \leq \frac{1}{|\Omega|}(1 + 4\epsilon^2)$  then  $D$  is  $\epsilon$ -uniform. It therefore follows that  $D_{E,X}$  is  $\epsilon$ -uniform where

$$\epsilon \leq \frac{1}{2} \sqrt{\frac{q}{|X|} + q\delta} = \sqrt{q\delta/2} \quad (3)$$

and  $E$  is a strong extractor.  $\square$

The original Johnson bound [20] was for binary codes and was later generalized to arbitrary alphabets (e.g., in [25]). Our framework allows us to generalize the the second bound in [25] to the soft-decision setting.

*Lemma IV.1:* (Johnson bound—soft-decoding setting) Let  $\mathcal{C}$  be a

$$\left[ T, k, \left( 1 - \frac{1}{q} - \delta \right) T \right]_q$$

code. Then for  $\epsilon > \frac{1}{2} \sqrt{q\delta}$ ,  $\mathcal{C}$  has  $(\frac{q}{4\epsilon^2 - q\delta}, \epsilon)$  soft decoding.

*Proof:* Let  $w : [T] \times \mathbb{F}_q \rightarrow [0, 1]$  be a weight function. Let  $\mathcal{A} = \mathcal{A}_\epsilon(w)$  and  $F, D_{F,\mathcal{A}}$  be as before. On the one hand, for every  $u \in \mathcal{A}$  we have  $\text{Ag}(u, w) > (\rho(w) + \epsilon)T$  and, therefore,

$|D_{F,\mathcal{A}} - U_{[T] \times [M]}| > \epsilon$ . On the other hand, from (3) it follows that

$$|D_{F,\mathcal{A}} - U_{[T] \times [M]}| \leq \frac{1}{2} \sqrt{\frac{q}{|\mathcal{A}|}} + q\delta.$$

Putting it together we see that  $|\mathcal{A}| < \frac{q}{4\epsilon^2 - q\delta}$ .  $\square$

A special case of the theorem is when  $q = 2$  and we look at regular list decoding. We then get that if the relative distance is  $\frac{1}{2} - \delta$  then any ball of relative radius  $\frac{1}{2} - \sqrt{\delta}$  contains at most  $\frac{1}{\delta}$  codewords, which is the original Johnson bound.

## V. REED-SOLOMON CODES

*Proof (of Theorem 3):* The proof uses the multiplicative subgroups of  $\mathbb{F}_M^*$ , an idea that was exploited in a more sophisticated way in [34].

For  $b_1 | M-1$ ,  $\mathbb{F}_M^*$  contains  $b_1$  distinct solutions to the equation  $x^{b_1} = 1$ . Denote these solutions by  $\{\alpha_1, \dots, \alpha_{b_1}\}$ , and define  $\alpha_0 = 0$ . Let

$$\mathcal{S} = \{(i, \alpha_j) : i \in [T], 0 \leq j \leq b_1\}, \quad |\mathcal{S}| = T(b_1 + 1)$$

and define the Boolean weight function  $w : [T] \times [M] \rightarrow \{0, 1\}$  to be one on  $\mathcal{S}$  and zero otherwise.

Let  $\mathcal{A}$  be the set of polynomials  $p^{b_2}$  for some  $p$  of degree at most  $\frac{c-1}{b_2}$ . For every  $q = p^{b_2} \in \mathcal{A}$  and  $i$ , either  $p(i) = 0$  and then  $q(i) = 0$  or  $p(i) \neq 0$  and then

$$(q(i))^{b_1} = (p(i))^{b_1 b_2} = (p(i))^{M-1} = 1$$

and so  $(i, q(i)) \in \mathcal{S}$ . Hence, if  $\mathcal{RS}(q)$  denotes the codeword corresponding to  $q$ ,  $\text{Ag}(\mathcal{RS}(q), \mathcal{S}) = T$ . Since distinct  $q$  of degree less than  $c$  give distinct codewords  $\mathcal{RS}(q)$ ,  $\mathcal{A}_{\max}(w) \geq |\mathcal{A}|$ , where  $\mathcal{A}_{\max}(w)$  is the set of all codewords  $u$  that have full agreement with  $w$ , i.e.,  $\text{Ag}(u, w) = T$ .

To lower-bound  $|\mathcal{A}|$ , note that  $\mathbb{F}_M[X]$  is a unique factorization domain, which implies that for each  $q \in \mathcal{A}$ , the  $p$  such that  $p^{b_2} = q$  is uniquely determined up to multiples of  $\mathbb{F}_M$ . Consequently, each  $q \in \mathcal{A}$  can arise from at most  $M$  polynomials  $p$  of degree at most  $\frac{c-1}{b_2}$  (in fact, at most  $b_2$  such polynomials). Therefore,  $|\mathcal{A}| \geq M^{1 + \frac{c-1}{b_2}} / M$ .  $\square$

## VI. EXTRACTORS AND PSEUDORANDOM GENERATORS

In this section, we show that extractors constructed via so-called black-box pseudorandom generators give extractor codes with efficient probabilistic soft decoding. In Section VII, we show how to make the soft decoding deterministic for one such extractor, Trevisan's extractor [21]. Section VII does not rely on this section, so some readers who wish to avoid more computer science terminology may skip directly to that section. However, we believe that this section is more basic. We begin with the necessary background.

### A. Background on Nonuniformity and Circuits

A nonuniform algorithm  $A$  is an infinite sequence of algorithms  $A_1, A_2, \dots$ , one for each input size. To run  $A$  on an input  $x$  of size  $n$ , we run  $A_n$  on  $x$ . As one might expect, an infinite sequence of algorithms is more powerful than one algorithm; intuitively, it may be hard to compute the algorithm  $A_n$  from  $n$ .

Traditionally, the  $A_i$  are modeled as circuits; here it is natural to have a different circuit for each input size. An equivalent way to model  $A$  is as a Turing machine with advice. On an input  $x$  of size  $n$ ,  $A$  receives some advice string  $a_n$  depending only on  $n$ ;  $A$  then performs its computation on  $x$  and  $a_n$ . One may think of  $a_n$  as a description of the circuit.

For more background in this area, we refer the reader to textbooks in computational complexity, such as [35].

### B. Pseudorandom Generators

A pseudorandom generator takes a short random string and expands it to a long string that looks random to all small circuits.

*Definition VI.1:* Let  $D_1, D_2$  be two distributions on  $\Omega$ . We say a circuit  $A$   $\epsilon$ -distinguishes  $D_1$  from  $D_2$  if

$$\left| \Pr_{x_1 \in D_1} [A(x_1) = 1] - \Pr_{x_2 \in D_2} [A(x_2) = 1] \right| \geq \epsilon.$$

If  $D_2$  is uniform on  $\Omega$  we say  $A$   $\epsilon$ -distinguishes  $D_1$  from uniform.

*Definition VI.2:*  $G : [T] \rightarrow [M]$  is a strong  $\epsilon$ -pseudorandom generator against size  $s$  circuits, if no size  $s$  circuit  $\epsilon$ -distinguishes the distribution  $U_{[T]} \circ G(U_{[T]})$  from uniform, where the distribution  $U_{[T]} \circ G(U_{[T]})$  is obtained by picking  $y$  uniformly from  $[T]$  and evaluating  $y \circ G(y)$ . (A pseudorandom generator without the word strong would only require that no small circuit distinguishes  $G(U_{[T]})$  from uniform.)

Note that for strong pseudorandom generators, we require the circuit size  $s$  to be smaller than the time to compute  $G$ ; otherwise, the circuit could compute  $G$  and distinguish the output from uniform.

Currently, no explicit pseudorandom generators are known. However, it is known how to build pseudorandom generators from a given hard function  $f$ . That is, there is a general construction  $G = G_f : [T] \rightarrow [M]$  that is guaranteed to be pseudorandom for small circuits whenever  $f$  is hard for small circuits. Such a construction first appeared in [36] and was later improved in [37], [38], [12]. A second construction appears in [30]. In these constructions, correctness is proved by proving the contrapositive. If  $G_f$  is *not* a pseudorandom generator, then by definition there exists a small circuit  $A$  distinguishing  $U_{[T]} \circ G_f(U_{[T]})$  from uniform. The proof then shows how to use the distinguisher  $A$  to build a small circuit for  $f$ . As  $f$  is hard for small circuits, one must conclude that  $G_f$  is pseudorandom.

A notable property of all current pseudorandom constructions is that they are *black-box*. This means that the generator  $G = G_f$  only needs black-box access to  $f$ , i.e., it only needs  $f$  values on given inputs, and otherwise does not use any other property of  $f$ . Similarly, the reconstruction algorithm that computes  $f$  using the distinguisher  $A$  only needs black-box access to evaluations of  $A$ , and otherwise does not use any other property of  $A$ . This is captured in the definition of a black-box pseudorandom generator later. Note that an *oracle* Turing machine (circuit) is a Turing machine (circuit) that has black-box access (also called oracle access) to a function.

*Definition VI.3:* A black-box generator is an oracle machine  $G^f : [T] \rightarrow [M]$ , with black-box access to a Boolean function

$f : [\log(C)] \rightarrow \{0, 1\}$ . We say  $G$  is efficient if it runs in time polynomial in its input length  $\log(T)$ .

*Definition VI.4:* A black-box reconstruction algorithm for  $G^f$  with  $a$  bits of advice, is an algorithm  $R$  that takes a short advice string  $\text{adv} = \text{adv}(f) \in \{0, 1\}^a$  and outputs an oracle circuit  $R(\text{adv})^A$ . Let  $\text{Time}(R)$  be the running time of  $R$  and  $\text{Size}(B)$  the size of the oracle circuit implementing  $B$ .  $R$  may be uniform or nonuniform, deterministic or probabilistic.

*Definition VI.5:* We say  $(G^f, R)$  is a black-box  $\epsilon$ -pseudorandom generator if for every Boolean function  $f : [\log(C)] \rightarrow \{0, 1\}$ , and every circuit  $A$   $\epsilon$ -distinguishing  $U_{[T]} \circ G^f(U_{[T]})$  from uniform, there exists an advice string  $\text{adv} = \text{adv}(f) \in \{0, 1\}^a$  such that  $R(\text{adv})^A = f$ . If  $R$  is probabilistic, this means that with high probability over the random coins of  $R$ , the output  $B = R(\text{adv})^A$  is an oracle circuit, that with oracle access to  $A$  correctly computes  $f$ .

Note that the definition of a black-box pseudorandom generator does not refer to the size of circuits. However, when we instantiate  $f$  to be a hard function for certain size circuits, we do obtain a pseudorandom generator for small circuits.

We now claim the following.

*Proposition VI.1:* ([36]) Let  $(G^f, R)$  be a black-box  $\epsilon$ -pseudorandom generator with  $B = R(\text{adv})^A$  the oracle circuit output by  $R$ . If  $f$  can not be computed by size  $s \cdot \text{Size}(B)$  circuits, then  $G^f$  is a strong  $\epsilon$ -pseudorandom generator for size  $s$  circuits.

*Proof:* Let  $f : [\log(C)] \rightarrow \{0, 1\}$  be an arbitrary Boolean function. If there exists a size  $s$  circuit  $A$   $\epsilon$ -distinguishing the distribution  $U_{[T]} \circ G^f(U_{[T]})$  from uniform, then given the right advice  $\text{adv} = \text{adv}(f)$ ,  $B^A = R(\text{adv})^A$  computes  $f$ . We can then take the oracle circuit for  $B$  and replace each oracle call to  $A$  with a size  $s$  circuit. We thus get a size  $\text{Size}(B) \cdot s$  circuit evaluating  $f$ , contradicting the hardness of  $f$ .  $\square$

Notice that for the proposition to be useful,  $\text{Size}(B)$  has to be small. On the other hand, the argument does not require that the reconstruction algorithm  $R$  be uniform or efficient.

### C. A Probabilistic Soft Decoding Algorithm

Trevisan showed that a black-box pseudorandom generator  $G^f$  gives rise to a strong extractor  $E : [C] \times [T] \rightarrow [M]$  defined by  $E(f, y) = G^f(y)$  [21]. Here,  $f \in [C]$  is identified with a function  $f : [\log(C)] \rightarrow \{0, 1\}$ . We rephrase his proof to say that the corresponding extractor code  $\mathcal{C}_E$ , defined by  $\mathcal{C}_E(f) = (G^f(y_1), \dots, G^f(y_T))$ , has good soft decoding. Further, we extend it to say that if the reconstruction procedure is efficient (and hence, the output circuit has small size  $\text{Size}(B)$ ), then the code has efficient soft decoding.

*Proposition VI.2:* Suppose  $(G^f, R)$  is a black-box pseudorandom generator with  $R$  using  $a$  bits of advice. Then the extractor code  $\mathcal{C}_E$  for  $E(f, y) = G^f(y)$  has  $(L = 2^a, \epsilon)$ -combinatorial soft decoding with respect to Boolean weight functions. If  $R$  is efficient, then so is this soft decoding.

It follows from Theorem 1 that  $E$  is a strong  $(2^a/\epsilon, 2\epsilon)$  extractor and  $\mathcal{C}_E$  has  $(2^a/\epsilon, 2\epsilon)$ -combinatorial soft decoding.  $\square$

*Proof:* Let  $w : [T] \times [M] \rightarrow \{0, 1\}$  be a Boolean weight function, and let  $W$  be a circuit computing  $w$ . Let  $\mathcal{A}$  be the set of functions corresponding to  $\mathcal{A}_\epsilon(w)$ , i.e., let  $\mathcal{A}$  be the set of all functions  $f \in C$  with  $\text{Ag}(\mathcal{C}(f), w) > (\rho(w) + \epsilon)T$ . Then for any  $f \in \mathcal{A}$ ,  $W$   $\epsilon$ -distinguishes  $U_{[T]} \circ G^f(U_{[T]})$ . This is because  $\Pr[W(U_{[T]}, U_{[M]}) = 1] = \rho(w)$  and

$$\begin{aligned} \Pr_{y \in U_{[T]}} [W(y, E(f, y)) = 1] &= \sum_y \frac{1}{T} w(y, E(f, y)) \\ &= \frac{\text{Ag}(\mathcal{C}(f), w)}{T}. \end{aligned}$$

Therefore, the reconstruction property implies that for every  $f \in \mathcal{A}$  there exists an advice string  $\text{adv} = \text{adv}(f)$  such that  $R(\text{adv}(f))^W = f$ . In particular, different functions  $f \in \mathcal{A}$  must have different advice strings  $\text{adv}(f)$ . We conclude that the number of functions in  $\mathcal{A}$  is at most  $2^a$ , as required.

If  $R$  is efficient, then the decoding algorithm is to cycle over all  $2^a$  advice strings  $\text{adv}$ . For each of the  $2^a$  functions  $f = R(\text{adv})^W$ , test if  $f \in \mathcal{A}$ , and if so, output  $\mathcal{C}(f)$ . By the previous argument, this outputs every codeword  $\mathcal{C}(f)$  with  $f \in \mathcal{A}$ . The running time is polynomial in  $L$  and the running time of  $R$  (since the size of  $R(\text{adv})$  is at most the running time of  $R$ ).  $\square$

We now extend the previous proposition to soft decoding with arbitrary weight functions.

*Proposition VI.3:* Suppose  $(G^f, R)$  is a black-box pseudorandom generator with  $R$  using  $a$  bits of advice, where  $R$  is efficient. Then the extractor code  $\mathcal{C}_E$  for  $E(f, y) = G^f(y)$  has  $(L = \frac{2^a}{\epsilon}, 2\epsilon)$  combinatorial soft decoding and efficient probabilistic  $2\epsilon$ -soft decoding.

*Proof:* As mentioned earlier, the combinatorial soft decoding follows from Proposition VI.2 and Theorem 1. We now describe the efficient decoding.

Let  $w : [T] \times [M] \rightarrow [0, 1]$  be a weight function. Define the probabilistic test  $W : [T] \times [M] \rightarrow \{0, 1\}$  that accepts  $(y, z) \in [T] \times [M]$  with probability  $w(y, z)$ . As before, let  $\mathcal{A}$  be the functions corresponding to  $\mathcal{A}_{2\epsilon}(w)$ . Then, for the same reason as in Proposition VI.2, for any  $f \in \mathcal{A}$ ,  $W$   $2\epsilon$ -distinguishes  $U_{[T]} \circ G^f(U_{[T]})$ . We are, therefore, in the same situation as in Proposition VI.2, but now we have a probabilistic distinguisher  $W$ . However, the property of the black-box pseudorandom generator only applies to deterministic circuits.

We get around this by viewing the probabilistic test  $W$  as a probability distribution over deterministic tests  $\{W_r\}$ , where  $r$  are the internal coins of  $W$ . As  $W$   $2\epsilon$ -distinguishes  $U_{[T]} \circ G^f(U_{[T]})$  from uniform, it must be that for at least  $\epsilon$  fraction of the random coins  $r$ ,  $W_r$   $\epsilon$ -distinguishes  $U_{[T]} \circ G^f(U_{[T]})$  from uniform. Let us call such an  $r$  good for  $f$ . If  $r$  is good for  $f$ , then the soft-decoding algorithm from Proposition VI.2 running on  $W_r$  will output  $f$ .

We therefore define our decoding algorithm to toss  $s = 2a/\epsilon^2$  random strings  $r_1, \dots, r_s$ . For each  $r$  in the sequence, run the decoding algorithm from Proposition VI.2 on  $W_r$ . For fixed  $f$ , the probability that none of  $r_1, \dots, r_s$  are good for  $f$  is at most  $(1 - \epsilon)^s \leq \exp(-2a/\epsilon)$ . Thus, this bounds the probability that  $f$  is not output. By the union bound, the probability there exists some  $f \in \mathcal{A}$  that is not output is at most  $L \exp(-2a/\epsilon) \leq 2^{-a}$ .  $\square$

## VII. A DETERMINISTIC SOFT-DECODING ALGORITHM

Proposition VI.3 gives us a *probabilistic* soft-decoding algorithm. Our next goal is to find a *deterministic* soft-decoding algorithm. Looking back at the decoding algorithm in Proposition VI.3 we see that the problem is it uses a probabilistic distinguisher  $A = \{A_r\}$ . While many choices for  $r$  work, some do not and the decoding algorithm then may (with very low probability, yet nonzero) sample  $r_1, \dots, r_s$  that are all bad.

To rectify this problem, we observe that current pseudo-random black-box generators are designed very much like concatenated codes. We then show how to reduce soft decoding of the concatenated code to soft decoding of the inner code. We take the inner code to be Reed–Solomon concatenated with Hadamard, and we show an explicit soft decoding for it. Together, we get a deterministic soft-decoding algorithm.

The above approach works for both Trevisan’s extractor and Shaltiel and Umans’ extractor. We work out the details for Trevisan’s extractor [21] because technically it is simpler.

### A. Weak Designs

We first present the extractor [21] following the somewhat improved version given in [39]. We begin with some definitions.

**Definition VII.1:** (Weak design) [39] A family of sets  $Z_1, Z_2, \dots, Z_m \subseteq [t]$  is a weak  $(s, \rho)$  design if

- 1)  $\forall i |Z_i| = s$ , and
- 2)  $\forall i, \sum_{j < i} 2^{|Z_i \cap Z_j|} \leq \rho \cdot (m - 1)$ .

We have the following.

**Lemma VII.1:** [39] For every  $s, m$ , and  $\rho > 1$ , there exists a weak  $(s, \rho)$  design  $Z_1, Z_2, \dots, Z_m \subseteq [t]$  with

$$t = \left\lceil \frac{s}{\ln \rho} \right\rceil \cdot s.$$

Such a family can be found in time  $\text{poly}(m, t)$ .

We introduce some notation for specifying substrings indexed by weak designs. For  $y = y_1 \dots y_t \in \{0, 1\}^t$  and  $Z = \{z_1, \dots, z_s\} \subseteq [t]$ , we denote by  $y|Z$  the nonnegative integer obtained by restricting  $y$  only to those entries that are in  $Z$ , i.e.,  $j = y|Z$  is the number whose binary representation is  $y_{z_1} y_{z_2} \dots y_{z_s}$ .

Also, for strings  $\beta \in \{0, 1\}^{t-s}$  and  $\gamma \in \{0, 1\}^s$ , we denote by  $\gamma^z \circ \beta^{[t] \setminus Z}$  the  $t$  bit long string that has  $\gamma$  in the locations indexed by  $Z$  and  $\beta$  in the other locations.

### B. Soft-Decoding Reed–Solomon Concatenated With Hadamard

We will need to use a soft-decodable binary code; we choose to use Reed–Solomon concatenated with Hadamard. Let  $\mathcal{RS}$  be an  $[n, k, n - k + 1]_n$  Reed–Solomon code. Let  $H$  be an  $[n, \log n, \frac{n}{2}]_2$  Hadamard code. The concatenated code  $\mathcal{BC}$  is an

$$\left[ \bar{n} = n^2, k \log n, \frac{n(n - k + 1)}{2} \right]_2$$

code. A simple calculation shows that if we introduce a new parameter  $\delta$  than  $\mathcal{BC}$  is an  $[\bar{n}, k, (\frac{1}{2} - \delta)\bar{n}]_2$  code with  $\delta = \frac{k}{2n}$  (and  $\bar{n} = O((\frac{k}{\delta})^2)$ ). The Johnson bound shows that  $\mathcal{C}$  has good

list decoding, and its generalization shows that  $\mathcal{C}$  has good soft decoding.

Explicit list decoding is also not hard. In [40], improved explicit list decoding is shown. A soft-decoding algorithm can be obtained in a standard way by first soft decoding the inner Hadamard code with brute force (the number of Hadamard codewords is only  $n$  so we can cycle over all of them) and then using list decoding for the outer Reed–Solomon code. Details follow.

**Lemma VII.2:** Let  $\mathcal{C} \subseteq [M]^T$  be the  $[\bar{n}, k, (\frac{1}{2} - \delta)\bar{n}]_2$  Reed–Solomon concatenated with Hadamard code as above,  $M = 2, T = \bar{n}$ . Then  $\mathcal{C}$  has  $4\delta^{1/4}$  efficient soft decoding.

*Proof:* We first define the soft-decoding algorithm, having black-box access to some weight function  $w : [T] \times [M] \rightarrow [0, 1]$ . We view the output bits as composed of  $\frac{\bar{n}}{n} = n$  blocks of length  $n$  each. For each block  $j$ , the weight function  $w$  induces a weight function  $w_j : [n] \times \{0, 1\} \rightarrow [0, 1]$  on the block, where  $w_j(i, \sigma)$  is the weight  $w$  gives to  $\sigma$  in the  $i$ th location of the  $j$ th block.

For each block  $j$ , we run a  $2\delta^{1/4}$  Hadamard soft decoding by brute force (i.e., by enumerating all  $n$  codewords in the Hadamard code, and checking the weights) and get a list  $S_j$  of all Hadamard codewords in  $\mathcal{A}_{2\delta^{1/4}}(w_j)$ . By Lemma IV.1,  $|S_j| \leq \frac{1}{s\sqrt{\delta}}$ . We now apply Theorem 2 and find all Reed–Solomon codewords with  $2\delta^{1/4}n$  agreement with the sets  $S_1, \dots, S_n$ .

Every codeword of  $\mathcal{C}$  that is also in  $\mathcal{A}_{2\delta^{1/4}}(w)$ , must have at least  $2\delta^{1/4}n$  blocks  $j$  that belong to  $\mathcal{A}_{2\delta^{1/4}}(w_j)$ , and therefore must appear in the soft-decoding output list. Also, the parameters were chosen such that  $2\delta^{1/4} \geq \sqrt{k|S|}$  (keeping in mind that  $\delta = \frac{k}{2n}$ ), and so by Theorem 2, the procedure outputs at most  $n$  codewords of  $\mathcal{C}$ , and the whole procedure is efficient.  $\square$

### C. Trevisan’s Extractor

Trevisan [21] constructed an extractor  $\text{TR}_{c,m,\epsilon}(x, y)$  as follows. Compute a weak  $(s, \rho)$  design  $Z_1, Z_2, \dots, Z_m \subseteq [t]$  as in Lemma VII.1. Encode the input  $x \in \{0, 1\}^c$  using the binary error correcting code  $\mathcal{BC}$  given in Lemma VII.2 to get a  $\bar{c} = \text{poly}(c, \frac{1}{\beta})$  long string  $\hat{x} = \mathcal{BC}(x)$ . Use the random string  $y$  to select  $m$  output bits from  $\hat{x}$ . The  $i$ th output bit is  $\hat{x}_j$ , where  $j = y|Z_i$ .

#### Trevisan’s extractor [21] $\text{TR}_{c,m,\epsilon}$ .

*Parameters:*  $c, m, \epsilon > 0, \rho = 2$ .

*Binary code:*  $\mathcal{BC}_{c,\delta} : \{0, 1\}^c \rightarrow \{0, 1\}^{\bar{c}}$  the binary code given by Lemma VII.2 with  $\delta = (\frac{\epsilon}{4m})^4$ .

*Weak Design:*  $(s, \rho)$  design  $Z_1, \dots, Z_m \subseteq [t]$ , with

- $s = \log \bar{c} = O(\log c + \log m + \log(\frac{1}{\epsilon}))$ ,
- $t = \lceil \frac{s}{\ln \rho} \rceil = O((\log c + \log m + \log(\frac{1}{\epsilon}))^2)$

*Input:*  $x \in \{0, 1\}^c$ .

*Random string:*  $y \in \{0, 1\}^t$ .

*Output:* The output has  $m$  bits

$$\text{TR}(x; y)_i = \hat{x}(y|Z_i)$$

where  $\hat{x} = \mathcal{BC}(x)$ .

Letting  $T = 2^t$  and  $M = 2^m$ , note that  $\mathcal{C}_{\text{TR}} \subseteq [M]^T$  is of size  $2^c$ .

#### D. Decoding $\mathcal{C}_{\text{TR}}$

We now describe the decoding algorithm for  $\mathcal{C}_{\text{TR}}$ .

##### Algorithm VII-D: Decoding $\mathcal{C}_{\text{TR}}$ .

*Input:*  $w : [T] \times [M] \rightarrow [0, 1]$ .

*Algorithm:* For every:

- $\alpha \in \{0, 1\}^m$ ,
- $\beta \in \{0, 1\}^{t-s}$ ,
- $1 \leq i \leq m$ ,
- set of possible truth tables  $P_1, \dots, P_{i-1}$ , where  $P_j$  has size  $2^{|Z_i \cap Z_j|}$ ,

define a weight function  $w_{\mathcal{BC}}$  for the binary code  $\mathcal{BC}$  as follows. For every  $\gamma \in \{0, 1\}^s$  and bit  $\in \{0, 1\}$ :

- Let  $y = \gamma^{Z_i} \circ \beta^{[t] \setminus Z_i}$ .
- Define  $b \in \{0, 1\}^m$  by

$$b_j = \begin{cases} P_j(y|_{Z_i \cap Z_j}) & \text{if } j < i \\ \text{bit} & \text{if } j = i \\ \alpha_j & \text{if } j > i \end{cases}$$

and we let  $w_{\mathcal{BC}}(\gamma, \text{bit}) = w(y, b)$ .

Find all codewords  $\hat{v} \in \mathcal{BC}$  with  $\text{Ag}(\hat{v}, w_{\mathcal{BC}}) \geq (\frac{1}{2} + \frac{\epsilon}{m}) \bar{c}$  and output the corresponding  $v \in \{0, 1\}^c$ .

*Lemma VII.3:* For every  $w : \{0, 1\}^t \times \{0, 1\}^m \rightarrow [0, 1]$  and every  $x \in \{0, 1\}^c$  for which  $\text{Ag}(x, w) \geq (\rho(w) + \epsilon)T$ ,  $x$  appears in the output list of Algorithm VII-D.

The proof follows the outline in Section VI, and is a ‘‘constructive’’ variation of Trevisan’s proof, giving an efficient algorithm ‘‘decoding’’ the extractor. A technical difference between this proof and Trevisan’s proof is that our decoding algorithm reduces to a soft-decoding algorithm of the binary code  $\mathcal{BC}$ .

*Proof of Lemma VII.3:* Fix any  $x \in \{0, 1\}^c$  such that  $\text{Ag}(x, w) \geq (\rho(w) + \epsilon)T$ . Define the probabilistic test

$$W : \{0, 1\}^{t+m} \rightarrow \{0, 1\}$$

which accepts  $(y, u)$  with probability  $w(y, u)$ . As before, let  $D_{\text{TR}, \{x\}}$  be the distribution  $U_{[T]} \circ \text{TR}(\{x\}, U_{[T]})$  obtained by picking  $y$  uniformly at random from  $\{0, 1\}^t$  and computing  $y \circ \text{TR}(x, y)$ .

We now define the reconstruction procedure  $R$ . Define the hybrid distributions  $D_0, \dots, D_m$  where  $D_i$  picks the first  $t+i$  bits from  $D_{\text{TR}, \{x\}}$  and the last  $m-i$  bits from  $U_{t+m}$ . We have

$$\Pr[W(D_0) = 1] = \Pr[W(U_{t+m}) = 1] = \rho(w)$$

and

$$\Pr[W(D_m) = 1] = \Pr[W(D_{\text{TR}, x}) = 1] \geq \rho(w) + \epsilon.$$

Therefore, there must be an  $i$ ,  $1 \leq i \leq m$ , such that

$$\Pr[W(D_i) = 1] \geq \Pr[W(D_{i-1}) = 1] + \frac{\epsilon}{m}.$$

In both  $D_{i-1}$  and  $D_i$ , the last  $m-i$  bits are uniform and independent of the rest. Hence, there exists a fixed string  $\alpha \in$

$\{0, 1\}^m$  such that fixing the last  $m-i$  bits to the last bits of  $\alpha$  preserves the gap of at least  $\epsilon/m$ .

We can also split  $y \in \{0, 1\}^t$  into those bits in locations indexed by  $Z_i$ , which we denote by  $\gamma$ , and the rest of the bits in locations  $[t] \setminus Z_i$  which we denote by  $\beta$  (and so  $y = \gamma^{Z_i} \beta^{[t] \setminus Z_i}$ ). Again, there is a way to fix  $\beta$  and still preserve the gap.

Furthermore, once  $\beta$  is fixed, the values  $\text{TR}(x, j)$  for  $j = 1, \dots, i-1$ , that appear on both distributions, depend only on the bits of  $\gamma$  and in a very weak way. In particular, there are truth tables  $P_1, \dots, P_{i-1}$  that describe these dependencies (the string describing the truth tables  $P_1, \dots, P_{i-1}$  corresponds to the advice string  $\text{adv} = \text{adv}(x)$  in Section VI).

Now, for the given  $x$  we have

$$\begin{aligned} & \Pr_{\gamma} [W(y \circ P_1(\gamma) \dots P_{i-1}(\gamma) \hat{x}(\gamma) \alpha_{i+1} \dots \alpha_m) = 1] \\ & \geq \Pr_{b_i \in \{0, 1\}, \gamma} [W(y \circ P_1(\gamma) \dots P_{i-1}(\gamma) b_i \alpha_{i+1} \dots \alpha_m) = 1] \\ & \quad + \frac{\epsilon}{m}. \end{aligned}$$

Now notice that  $\mathbf{E}_{\gamma \in \{0, 1\}^s} [w_{\mathcal{BC}}(\gamma, \hat{x}_{\gamma})]$  is

$$\Pr_{\gamma} [W(y \circ P_1(\gamma) \dots P_{i-1}(\gamma) \hat{x}_{\gamma} \alpha_{i+1} \dots) = 1]$$

and  $\mathbf{E}_{\text{bit} \in \{0, 1\}, \gamma} [w_{\mathcal{BC}}(\gamma, \text{bit})]$  is

$$\Pr_{b_i \in \{0, 1\}, \gamma} [W(y \circ P_1(\gamma) \dots P_{i-1}(\gamma) b_i \alpha_{i+1} \dots) = 1].$$

We therefore conclude that

$$\mathbf{E}_{\gamma} [w_{\mathcal{BC}}(\gamma, \hat{x}_{\gamma})] \geq \mathbf{E}_{\text{bit} \in \{0, 1\}, \gamma} [w_{\mathcal{BC}}(\gamma, \text{bit})] + \frac{\epsilon}{m}$$

which means that

$$\frac{\text{Ag}(\hat{x}, w_{\mathcal{BC}})}{\bar{c}} \geq \rho(w_{\mathcal{BC}}) + \frac{\epsilon}{m}.$$

Since  $\frac{\epsilon}{m} \geq 4\delta^{1/4}$  Lemma VII.2 asserts that  $x$  appears in the output.  $\square$

The number of elements in the output list is at most  $2^m \cdot 2^t \cdot m \cdot 2^{\rho m} \cdot O(\frac{m}{\epsilon})^4$  because we have  $2^m$  possibilities for  $\alpha$ ,  $2^t$  possibilities for  $\beta$ ,  $m$  possibilities for  $i$ , and  $2^{\rho m}$  possibilities for the tables  $P_1, \dots, P_{i-1}$ , and then we get at most  $\frac{1}{\delta} = O((\frac{m}{\epsilon})^4)$  possible answers (see Lemma VII.2). Taking  $\rho = 2$ ,  $c \leq M$  we get a running time of poly  $(M, T, \frac{1}{\epsilon})$ , which completes the proof of Theorem.

## VIII. HARDCORE BITS

One-way functions and their hardcore bits are key tools in cryptography. Informally, a one-way function  $f$  is easy to compute but hard to invert. By inverting  $z$  we mean finding any element of  $f^{-1}(z)$ . A function  $h$  on the same domain as  $f$  is hardcore for  $f$  if all statistical information about  $h(x)$  is hard to predict even given  $f(x)$ . We usually allow  $h$  to also have access to auxiliary randomness. We formalize all this as follows.

*Definition VIII.1:*  $f : [C] \rightarrow S$  is a one-way function with security  $(K, \epsilon)$  if  $f$  is computable in time  $\sqrt{K}$  but no probabilistic algorithm running in time  $K$  can invert  $f$  with probability at least  $\epsilon$ , where the probability is over a random input and the coins of the inverting algorithm.

Typically, the time to invert  $f$  is conjectured to be superpolynomial in the time to compute  $f$ , but we only need the above small difference for our result.

*Definition VIII.2:* Let  $f : [C] \rightarrow S$  be a function.  $h : [C] \times [T] \rightarrow [M]$  is a hardcore function for  $f$ , with security  $(K, \epsilon)$ , if there is no probabilistic algorithm running in time  $K$  that  $\epsilon$ -distinguishes<sup>2</sup> the distributions

$$(f(C), U_{[T]}, h(C, U_{[T]})) \quad \text{and} \quad (f(C), U_{[T]}, U_{[M]})$$

where  $(f(C), U_{[T]}, h(C, U_{[T]}))$  is the distribution obtained by picking  $c$  uniformly from  $C$ ,  $y$  uniformly from  $[T]$ , and evaluating  $(f(c), y, h(c, y))$ , and  $(f(C), U_{[T]}, U_{[M]})$  is the distribution obtained by picking  $c$  uniformly from  $C$ ,  $y$  uniformly from  $[T]$ ,  $z$  uniformly from  $[M]$ , and evaluating  $(f(c), y, z)$ .

We say  $h$  is *hardcore* with security  $(K, \epsilon)$  if it is hardcore with security  $(K, \epsilon)$  for all one-way functions with security  $(K^4, \frac{\epsilon}{4})$ .

Goldreich and Levin [4] showed that for  $T = C = \{0, 1\}^c$ , the function  $h(x, y) = \oplus_i x_i y_i$  is a hardcore bit (with  $M = \{0, 1\}^{m=1}$ ). Note that this requires as many auxiliary random bits  $y$  as input bits  $x$ , and that the hardcore function has only one output bit.

Impagliazzo [41] noticed that this is a special case of a generic construction based on list decodable codes. Let  $\mathcal{C} : [C] \rightarrow \{0, 1\}^T$  be a list decodable binary code. Then  $h(x, y) = \mathcal{C}(x)_y$  (the  $y$ th bit of the encoding of  $x$ ) is a hardcore predicate. Thus, the Goldreich and Levin result can be viewed as a list decoding algorithm for the Hadamard code. Moreover, by using list decodable binary codes with better rate, such as Reed–Solomon concatenated with Hadamard, a hardcore bit can be obtained with few auxiliary random bits. The hardcore function, though, still has only one output bit.

The main point of this section is to obtain many hardcore bits using small auxiliary randomness. This follows from our observation that Impagliazzo's construction generalizes to the case of more output bits. To get more bits, we choose a code over a larger alphabet,  $\mathcal{C} : [C] \rightarrow [M]^T$ , and the hardcore bits are  $h(x, y) = \mathcal{C}(x)_y$ . The notion of soft list decoding turns out to be what is needed here.

*Theorem 4:* Let  $\mathcal{C} : [C] \rightarrow [M]^T$  be a code with an  $\frac{\epsilon}{4}$  soft-decoding algorithm, running in time  $K$ ,  $\epsilon \geq 1/K$ . Then  $h(x, y) = \mathcal{C}(x)_y$  is hardcore with security  $(K, \epsilon)$ .

*Proof:* Suppose there exists a one-way function  $f$  with security  $(K^4, \epsilon/4)$  and a statistical (possibly probabilistic) test  $D$  which takes time  $K$  and  $\epsilon$ -distinguishes the distributions  $(f(C), U_{[T]}, h(C, U_{[T]}))$  and  $(f(C), U_{[T]}, U_{[M]})$ . We now give an inversion algorithm for  $f$ . The inversion algorithm is given an input  $z \in S$  to invert. We first define a weight function  $w = w_z : [T] \times [M] \rightarrow [0, 1]$  by letting  $w(y, v)$  be the probability that  $D$  accepts the input  $(z, y, v)$ . As  $D$  may be probabilistic, we do not have direct access to  $w$ . Nevertheless, we can estimate  $w(y, v)$  by random sampling, and in particular, if we run  $D$  on a given  $(z, y, v)$   $O(K \log K)$  times, with

probability  $1 - \frac{1}{2K}$ , we can obtain an estimate  $\hat{w}(y, v)$  which differs from  $w(y, v)$  by at most  $\frac{1}{2K} \leq \frac{\epsilon}{4}$ .

On input  $z$ , our inversion algorithm runs the  $\frac{\epsilon}{4}$  soft-decoding algorithm for  $\mathcal{C}$  with estimated weight function  $\hat{w} = \hat{w}_z$  to output a list of candidates. For each candidate  $c$  it tests if  $f(c) = z$  and outputs the first such  $c$  if it exists.

We now analyze the running time. The decoding algorithm runs in time  $K$  given access to  $\hat{w}$ . Since each access to  $\hat{w}$  is computed by  $O(K \log K)$  accesses to  $W$ , each of which in turn takes time  $K$ , the total running time of the decoding algorithm is

$$K \cdot O(K \log K) \cdot K = O(K^3 \log K).$$

The candidate list has size at most  $K$ , since the decoding algorithm itself runs in time  $K$  except for accesses to  $\hat{w}$ . Therefore, the running time for the candidate checks is at most  $K \cdot \sqrt{K^4} = K^3$ . Thus, the total running time is  $o(K^4)$ .

We now show that the algorithm inverts many inputs  $z$ . We know that  $D$   $\epsilon$ -distinguishes the distributions  $(f(C), U_{[T]}, h(C, U_{[T]}))$  and  $(f(C), U_{[T]}, U_{[M]})$ . Say, without loss of generality, that  $D$  accepts  $(f(C), U_{[T]}, h(C, U_{[T]}))$  more often than  $(f(C), U_{[T]}, U_{[M]})$ , i.e.,

$$\mathbf{E}_{\substack{c, y \\ z=f(c)}} w_z(y, h(c, y)) \geq \mathbf{E}_{y, v} w_z(y, v) + \epsilon = \rho(w_z) + \epsilon.$$

Equivalently

$$\mathbf{E}_c \left[ \frac{\text{Ag}(\mathcal{C}(c), w_z)}{T} \right] \geq \rho(w_z) + \epsilon.$$

An averaging argument then gives that there is a set  $\mathcal{A}$  of size at least  $\frac{\epsilon}{2}C$ , such that for all  $c \in \mathcal{A}$

$$\frac{\text{Ag}(\mathcal{C}(c), w_z)}{T} \geq \rho(w_z) + \frac{\epsilon}{2}. \quad (4)$$

Now, say  $z$  is of the form  $z = f(c)$  for  $c \in \mathcal{A}$ . Then, with probability at least  $1 - K \cdot \frac{1}{2K} = \frac{1}{2}$ , all the estimated weights  $\hat{w}_z(y, v)$  will be within  $\epsilon/4$  of the true weight  $w_z(y, v)$ . Since we output all  $c$  such that

$$\frac{1}{T} \text{Ag}(\mathcal{C}(c), \hat{w}_z) \geq \rho(\hat{w}_z) + \frac{\epsilon}{4}$$

if our estimates are accurate and our input is  $z = f(c)$  for  $c \in \mathcal{A}$ , then  $c$  will appear in the candidate list. Hence, with probability at least  $\frac{1}{2}$  some element of  $f^{-1}(z)$  will be output. Since  $\mathcal{A}$  constitutes an  $\epsilon/2$  fraction of all inputs and our algorithm runs in time  $o(K^4)$ , this contradicts the security of  $f$ . We conclude that  $h$  is hardcore.  $\square$

We can now use the extractor code  $\mathcal{C}_{\text{TR}}$  to obtain a hardcore function outputting many bits with few auxiliary random bits.

*Theorem 5:* There exists a constant  $\alpha > 0$  such that

$$\text{TR}_{c, m=\alpha k, \epsilon=\frac{1}{m}} : [C] \times [T] \rightarrow [M = K^\alpha]$$

defined in Section VII, is hardcore with security  $(K = 2^k, \epsilon)$ . Furthermore, the function uses only  $t$  auxiliary randomness where  $t \leq O((\log c + \log(\frac{1}{\epsilon}))^2)$ .

*Proof:* We have  $T \leq M$  and  $\epsilon = \frac{1}{M}$  and so the decoding running time is bounded by  $p(M)$  for some polynomial  $p(\cdot)$ . We choose  $M$  so that  $p(M) \leq K$ , which holds as long as  $m \leq \alpha k$  for some constant  $\alpha < 1$ , and then the decoding running time

<sup>2</sup>Recall that  $\epsilon$ -distinguishing was defined in Definition VI.1

is at most  $K$ . By Theorem 4, the function TR is hardcore with security  $(K, \epsilon)$ . The number of truly random bits used for these parameters is  $t = O(\log^2(\frac{\epsilon}{\epsilon}))$ .  $\square$

The function TR is hardcore for all one-way functions with security  $(K^4, \frac{\epsilon}{4})$ . We can think of a one-way function with security  $(K^4, \frac{\epsilon}{4})$  as having “hardness”  $4k$ . We therefore see that for every such  $f$  the function TR outputs a constant fraction of the hardness of  $f$ , and does so while using only very few auxiliary random bits. Thus, the hardcore function TR uses few random bits and outputs an almost optimal number of hard bits.

#### ACKNOWLEDGMENT

The authors wish to thank Madhu Sudan for his suggestion to generalize list decoding results they had to soft-decoding results. They would also like to thank Muli Safra, Venkatesh Srinivasan, Madhu Sudan, and Umesh Vazirani for helpful discussions and comments. The authors would also like to thank the anonymous referees for many very helpful comments to improve the presentation of the paper.
